Advanced SQL

06 — Recursion

Summer 2024

Torsten Grust
Universität Tübingen, Germany

Computational Limits of SQL

SQL has grown to be an **expressive data-oriented language.** Intentionally, it has *not* been designed as a general-purpose programming language:

1. *SQL does not loop forever:*
   Any SQL query is expected to **terminate**, regardless of the size/contents of the input tables.

2. *SQL can be **evaluated efficiently**:*
   A SQL query over table T of c columns and r rows can be evaluated in $O(r^c)$ space and time.[1]

[1] SQL cannot compute the set of all subsets (*i.e.*, the powerset) of rows in T which requires $O(2^r)$ space, for example.

A Giant Step for SQL

The addition of **recursion** to SQL changes everything:

Expressiveness SQL becomes a **Turing-complete language** and thus a general-purpose PL (albeit with a particular flavor).

Efficiency ⚠️ **No longer** are queries guaranteed to **terminate** or to be **evaluated with polynomial effort.**

Like a pact with the 👿 — but the payoff is magnificient…

Recursion in SQL: WITH RECURSIVE

Recursive common table expresssion (CTE):

$$
\begin{array}{ll}
\texttt{WITH RECURSIVE} & \\
\quad T_1(c_{11},\ldots,c_{1,k1})\ \texttt{AS} & \\
\qquad (q_1), & \\
\quad\ \vdots & \text{Queries } q_j \text{ may refer } \textbf{\textit{to all}}\ T_i \\
\quad T_n(c_{n1},\ldots,c_{n,kn})\ \texttt{AS} & \\
\qquad (q_n) & \\
q & \}\ q \text{ may refer } \textbf{\textit{to all}}\ T_i
\end{array}
$$

- In particular, any q_j may refer to itself (⟲)! Mutual references are OK, too. (Think letrec in FP.)

- Typically, final query q performs post-processing only.

Shape of a Self-Referential Query

WITH RECURSIVE
  $T(c_1,\ldots,c_k)$ **AS** -- common schema of q_0 and $q{\circlearrowleft}(\cdot)$
   $(q_0$ -- base case query, evaluated once

    UNION [ALL] -- either **UNION** or **UNION ALL**

    $q{\circlearrowleft}(T)$ -- recursive query refers to T
   $)$ --   itself, evaluated repeatedly
$q(T)$ -- final post-processing query

- Semantics in a nutshell:

$$q(\ q_0 \cup \underbrace{q{\circlearrowleft}(q_0) \cup q{\circlearrowleft}(q{\circlearrowleft}(q_0)) \cup \cdots \cup q{\circlearrowleft}(\cdots q{\circlearrowleft}(q{\circlearrowleft}(q_0))\cdots)}_{\text{repeated evaluation of } q{\circlearrowleft} \text{ (when to stop?)}}\ )$$

Semantics of a Self-Referential Query (UNION Variant)

Iterative and recursive semantics—both are equivalent:

```
iterate(q⟲, q₀):                 recurse(q⟲, r):
  r ← q₀                            if r ≠ ∅ then
  t ← r                             │ return r ⊎ recurse(q⟲, q⟲(r) \ r)
  while t ≠ ∅                       else
  │ t ← q⟲(t) \ r                   └ return ∅
  └ r ← r ⊎ t
  return r
```

- Invoke the recursive variant with $\mathrm{recurse}(q^{\circlearrowleft}, q_0)$.
- $\uplus$ denotes disjoint set union, $\setminus$ denotes set difference.
- $q^{\circlearrowleft}(\cdot)$ is evaluated over **the *new* rows found in the last iteration/recursive call.** Exit if there were no new rows.

A Home-Made generate_series()

Generate a single-column table series of integers $i \in \{from, from+1, \ldots, to\}$:

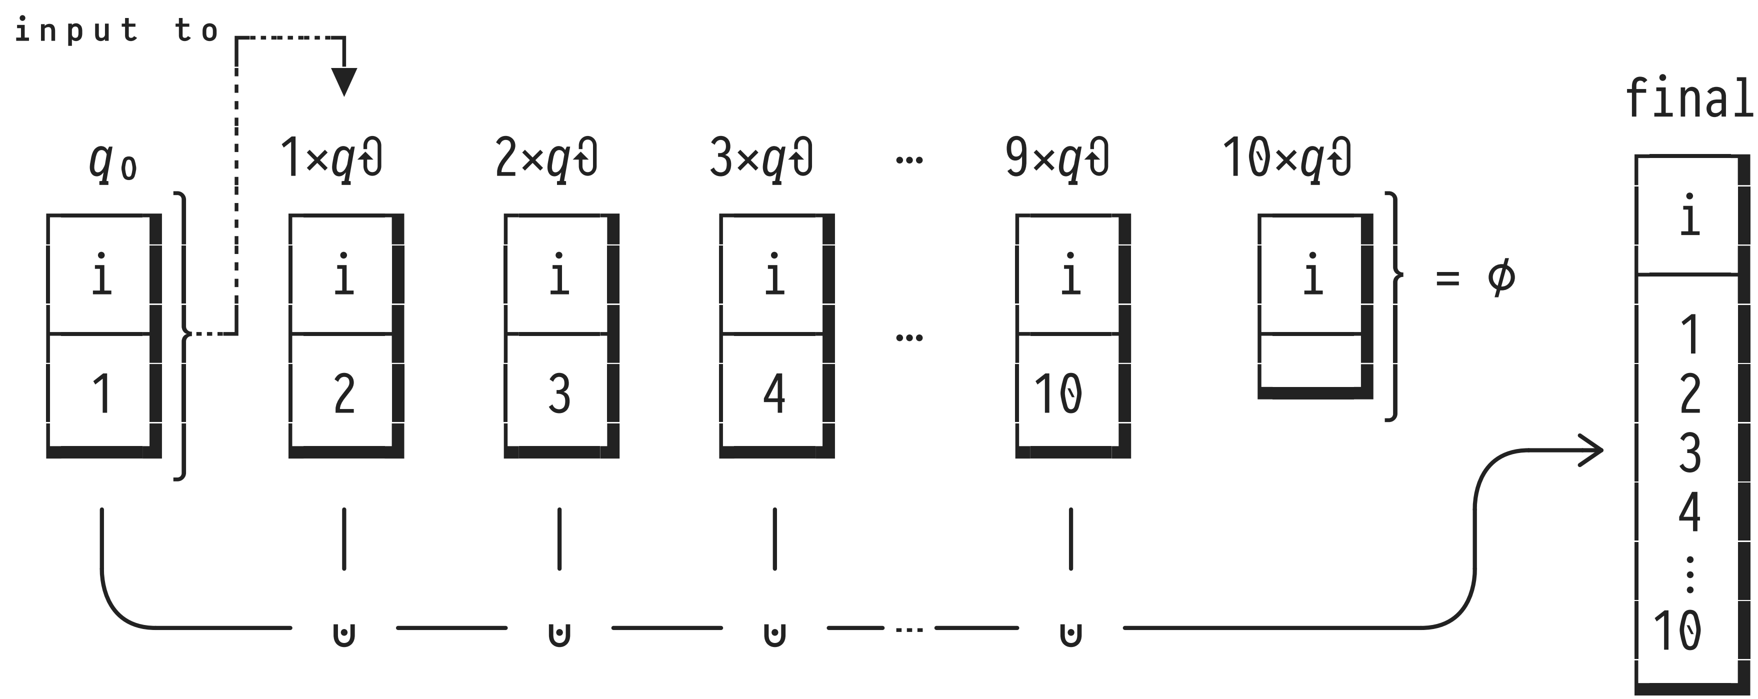
```
WITH RECURSIVE
  series(i) AS (
  ▲ VALUES (from)              -- q₀
  ┊     UNION
  ┊ SELECT s.i + 1 AS i        -- ⎫                    ▲   self-
  └╌FROM╌╌╌╌▶series AS s       -- ⎬ q⟲(series)         ┊   reference
    WHERE  s.i < to            -- ⎭                    └╌╌▶
)
TABLE series
```

- **Q:** Given the predicate $s.i < to$, will to indeed be in the final table?

A Home-Made generate_series()

- Assume *from* = 1, *to* = 10:

New rows in table **series** after evaluation of…



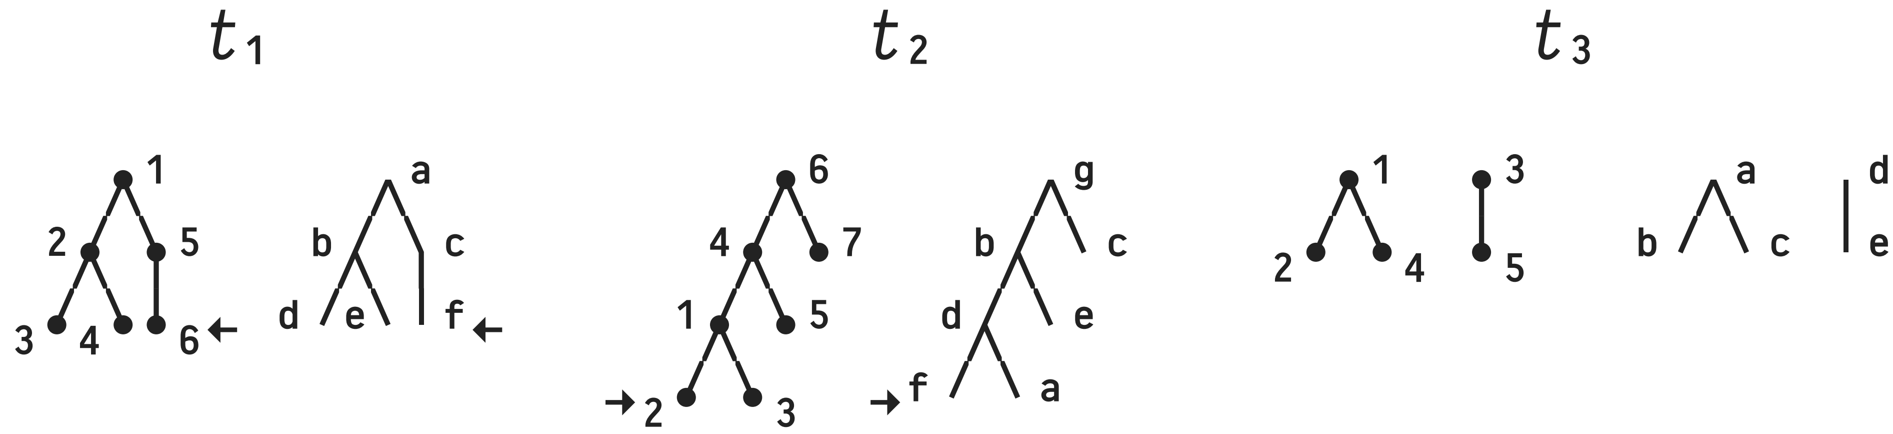
Semantics of a Self-Referential Query (UNION ALL Variant)

With UNION ALL, recursive query $q\circlearrowleft$ sees ***all* rows added in the last iteration/recursive call:**

```
iterate^all(q↺, q₀):              recurse^all(q↺, r):
  r ← q₀                            if r ≠ ∅ then
  t ← r                             | return r ⊎ recurse^all(q↺, q↺(r))
  while t ≠ ∅                       else
  | t ← q↺(t)                       ⌊ return ∅
  ⌊ r ← r ⊎ t
  return r
```

- Invoke the recursive variant via $\text{recurse}^{\text{all}}(q\circlearrowleft, q_0)$.
- $\uplus$ denotes bag (multiset) union.
- Note: Could immediately emit t—no need to build r. 👍

1 ┆ Traverse the Paths from Nodes 'f' to their Root



Array-based tree encoding (parent of node n ≡ parents[n]):

tree	parents (□ ≡ NULL)	labels
t_1	[□, 1, 2, 2, 1, 5]	['a','b','d','e','c','f']
t_2	[4, 1, 1, 6, 4, □, 6]	['d','f','a','b','e','g','c']
t_3	[□, 1, □, 1, 3]	['a','b','d','c','e']
	1 2 3 4 5 6 7	1 2 3 4 5 6 7 ← node

Trees

Traverse the Paths from Nodes 'f' to their Root

```
WITH RECURSIVE
  paths(tree, node) AS (
    SELECT t.tree, list_position(t.labels, 'f') AS node
    FROM   Trees AS t
    WHERE  'f' = ANY(t.labels)

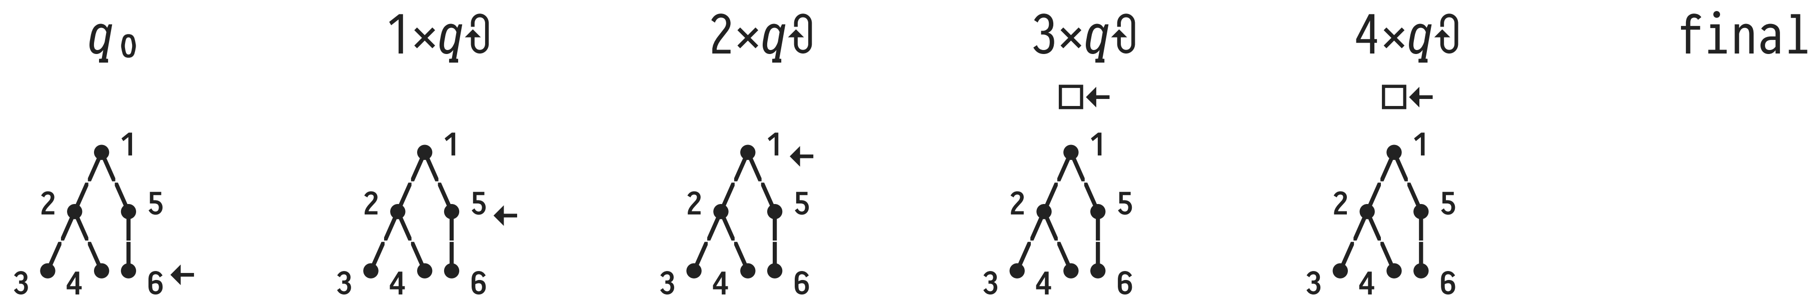
      UNION

    SELECT t.tree, t.parents[p.node] AS node
    FROM   paths AS p,
           Trees AS t
    WHERE  p.tree = t.tree
)
TABLE paths
```

$(t, n) \in$ paths $\Leftrightarrow$ node n lies on path from '**f**' to t's root

A Trace of the Path in Tree t_1

New rows produced by…



q_0:

tree	node
t_1	6

$1{\times}q\vartheta$:

tree	node
t_1	5

$2{\times}q\vartheta$:

tree	node
t_1	1

$3{\times}q\vartheta$:

tree	node
t_1	□

$4{\times}q\vartheta$:

tree	node

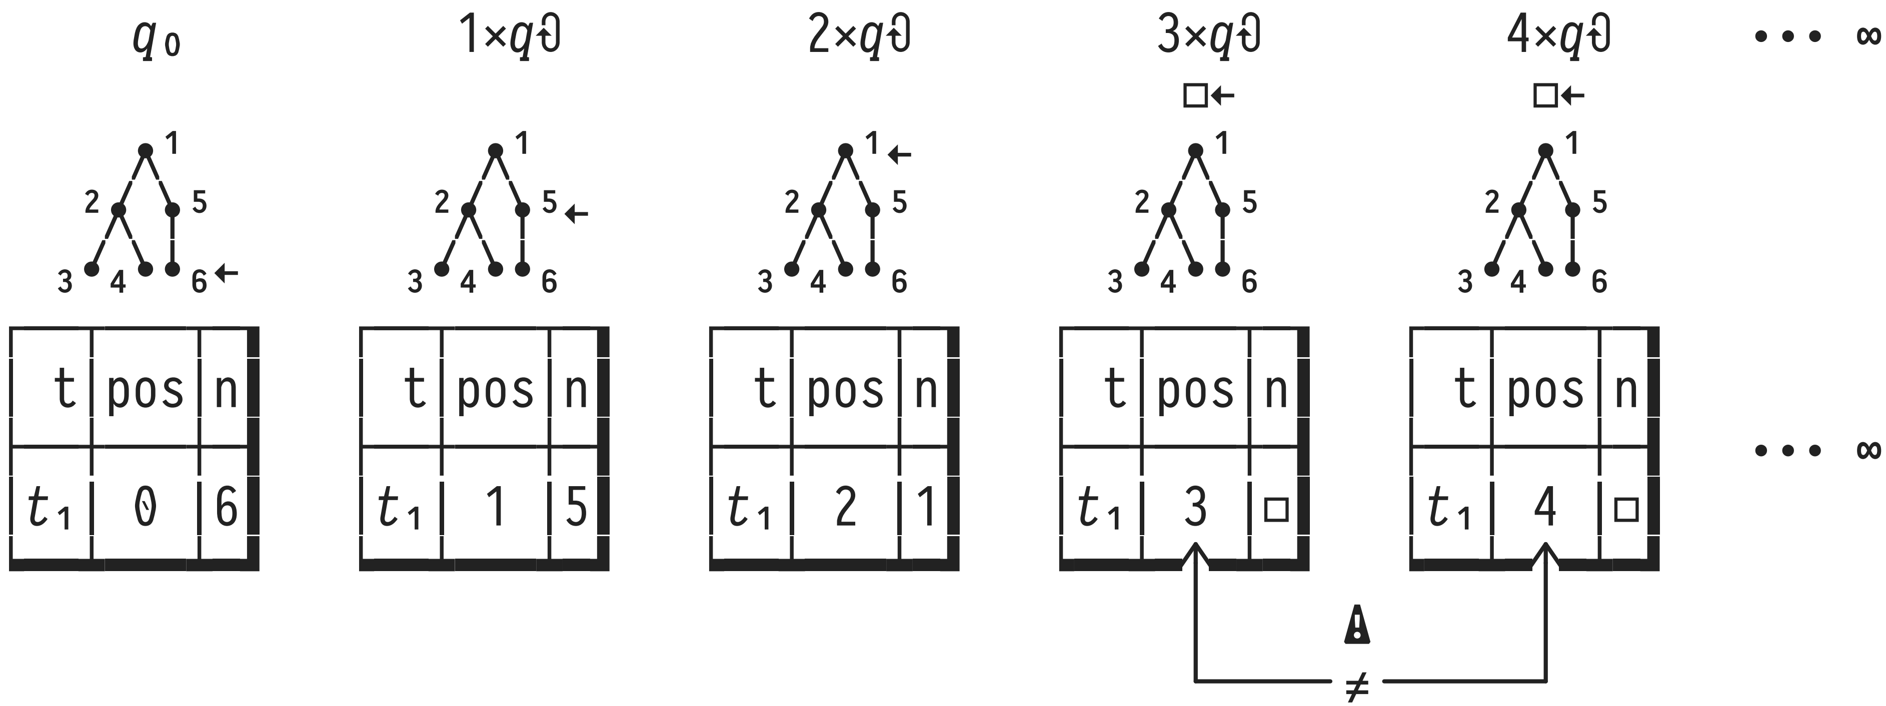
⊎ ⊎ ⊎

final:

tree	node
t_1	6
t_1	5
t_1	1
t_1	□

- $4{\times}q\vartheta$ yields no new rows (recall: `t.parents[NULL] ≡ NULL`).

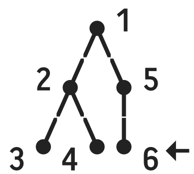
Ordered Path in Tree t_1 (New Rows Trace)



The **(non-)generation of new rows to ensure termination** is the user's responsibility—a common source of bugs.

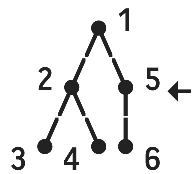
Path as Array in Tree t_1 (New Rows Trace)

q_0



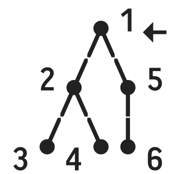
t	n	path
t_1	6	[]

$1\times q^{\circlearrowleft}$



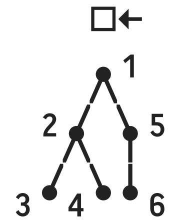
t	n	path
t_1	5	[6]

$2\times q^{\circlearrowleft}$



t	n	path
t_1	1	[6,5]

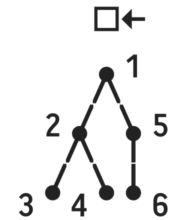
$3\times q^{\circlearrowleft}$



t	n	path
t_1	□	[6,5,1]

❷

(*not generated*

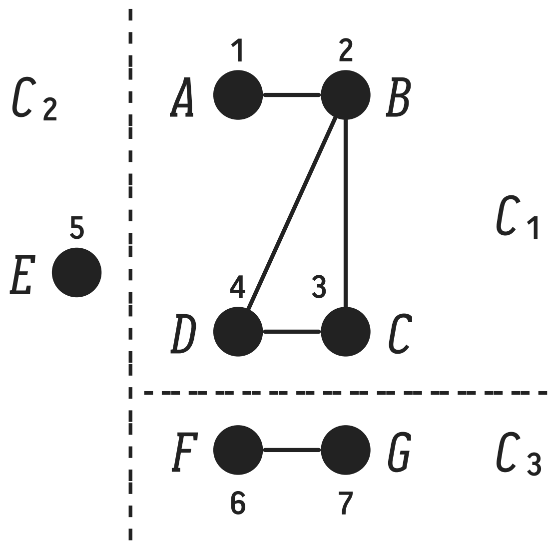


t	n	path
t_1	□	[6,5,1,□]

❶)

❶ Ensure termination (enforce ϕ): filter on $n \neq □$ in $q^{\circlearrowleft}$.

❷ Post-process: keep rows of last iteration ($n = □$) only.



- Given an undirected graph G, find its **connected components** C_i:

  For any two nodes v_1,v_2 in C_i, there exists a path v_1—v_2 (and no connections to outside C_i exist).

- Do we need DBMSs tailored to process graph data and queries?

Graphs are (edge) *relations*. Connected components are the equivalence classes of the reachability *relation* on G.

Representing (Un-)Directed Graphs

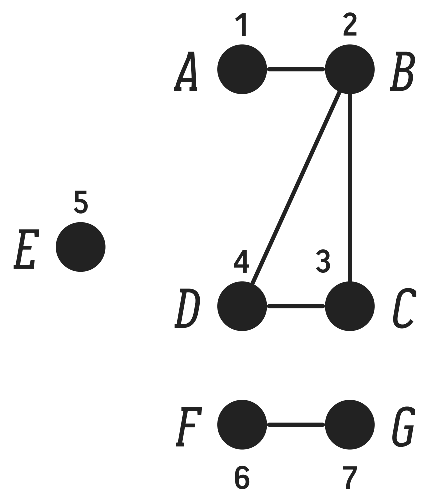
A ⇆ *B*
A — *B*

- Use tables nodes and graph to formulate the algorithm.

🔧 Computing Connected Components (Query Plan)



1. For each node n, start a **walk** through the graph. Record each node f ("front") that we can **reach** from n.

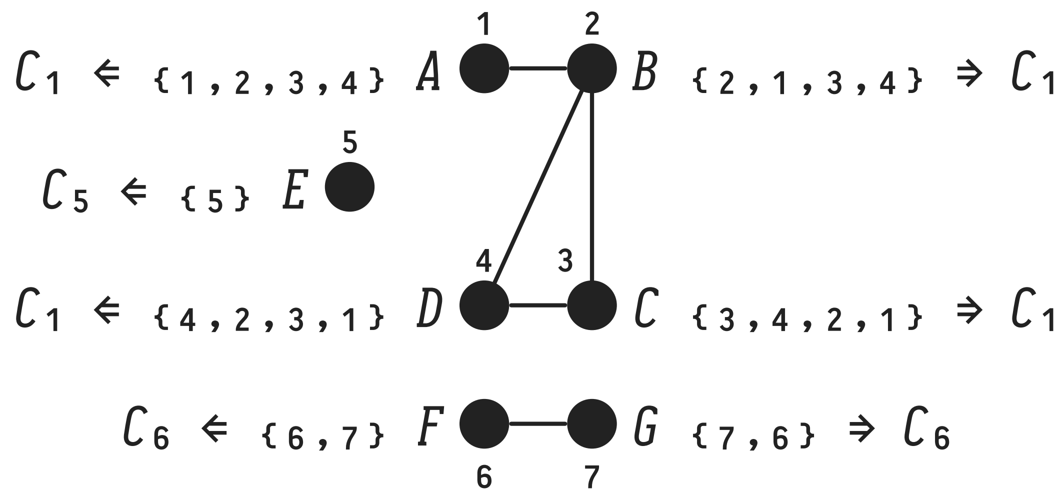
2. For each n, assign the **minimum ID** i of all front nodes as n's component C_i.

   ⇒ Nodes that can reach each other will use the same component ID.

⚠️ In Step 1, take care to not walk into **endless cycles**.

Computing Connected Components (Query Plan)

- {…}: Reachable front nodes, C_i derived component ID:



- Tasks for further post-processing:
  - Assign sane component IDs (C_1,C_2,C_3).
  - Extract subgraphs based on components' node sets.

Recursive Graph Walks, From All Nodes at the Same Time

```
WITH RECURSIVE

walks(node, front) AS (
  SELECT n.node, n.node AS front  -- (n,n) ∊ walks: we can
  FROM   nodes AS n               -- reach ourselves

    UNION      -- only new front nodes will be recorded ✓

  SELECT w.node, g."to" AS front  -- record front node
  FROM   walks AS w, graph AS g   -- ⎫ finds all incident
  WHERE  w.front = g."from"       -- ⎭ graph edges
)
```

Invariant: If $(n,f) \in$ walks, node f is reachable from n.

Recursive Graph Walks, From All Nodes at the Same Time

3×q↺

node	front

- Tree path finding and connected component search used **node adjacency information** to explore graph structure, iteration by iteration.

- In a variant of this theme, let us view **text as lists of adjacent characters** that we recursively explore.

- We particularly use the observation (let s :: text, $n \geqslant 1$):

$$s = \underbrace{\text{left}(s,\ n)}_{\text{prefix of } s \text{ of length } n} \;||\; \underbrace{\text{right}(s,\ -n)}_{\text{all but the first } n \text{ chars of } s}$$

Set-Oriented (Bulk) Regular Expression Matching

Goal: Given a—potentially large—table of input strings, **validate all strings against a regular expression:**[2]

input
s_1
s_2
$\vdots$
s_n

$\longrightarrow$

input	parse?
s_1	✓
s_2	✗
$\vdots$	$\vdots$
s_n	✓

- Plan: Parse all s_i in parallel (run n matchers at once).

[2] Later on, we consider parsing given a context-free grammar.

Breaking Bad

Match the **formulæ of chemical compounds** against the regular expression:

$$([A\ldots Za\ldots z]+[_{0}\ldots_{9}]*([^{0}\ldots^{9}]*[^{+-}])?)+$$

compound	formula
citrate	$C_6H_5O_7{}^{3-}$
glucose	$C_6H_{12}O_6$
hydronium	H_3O^+
⋮	⋮

Table compounds

- Generally: support regular expressions re of the forms c, $[c_1c_2\ldots c_n]$, re_1re_2, $re*$, $re+$, $re?$, $re_1|re_2$.

From Regular Expression to Finite State Machine (FSM)

- Represent *re* in terms of a **deterministic FSM:**

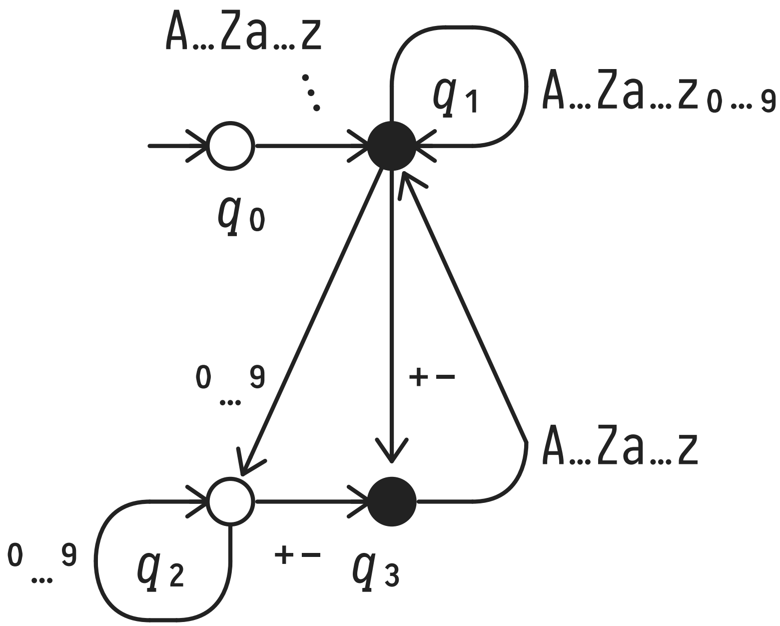

Table **fsm**

source	labels	target	final?
q_0	A…Za…z	q_1	false
q_1	A…Za…z0…9	q_1	true
q_1	0…9	q_2	true
q_1	+-	q_3	true
q_2	0…9	q_2	false
q_2	+-	q_3	false
q_3	A…Za…z	q_1	true

- We tolerate the non-key-FD source→final? for simplicity.

Driving the Finite State Machines (Query Plan)

1. For n entries in table compounds, operate n instances of the FSM “in parallel”:
    - Each FSM instance maintains its current state and the residual input still to match.

2. **Invariant:**

compound	step	state	input
c	s	q	f

Table match

- After $s \geqslant 0$ transitions, FSM for compound c has reached state q. Residual input is f (a suffix of c's formula).

🔧 Driving the Finite State Machines (SQL Code)

```
WITH RECURSIVE
match(compound, step, state, input) AS (
 SELECT c.compound, 0 AS step, 0 AS state,
        c.formula AS input  --
 FROM   compounds AS c      --   state q₀

   UNION ALL -- ⚠️  bag semantics (see below)

 SELECT m.compound, m.step + 1 AS step, f.target AS state,
        right(m.input, -1) AS input
 FROM   match AS m, fsm AS f
 WHERE  length(m.input) > 0
 AND    m.state = f.source
 AND    contains(f.labels, left(m.input, 1))
)
```

Matching Progess (by Compound / by Step)

❶ Focus on indivdiual compound

compound	step	state	input
citrate	0	0	$C_6H_5O_7^{3-}$
citrate	1	1	$_6H_5O_7^{3-}$
citrate	2	1	$H_5O_7^{3-}$
citrate	3	1	$_5O_7^{3-}$
citrate	4	1	O_7^{3-}
citrate	5	1	$_7^{3-}$
citrate	6	1	$^{3-}$
citrate	7	2	$^{-}$
citrate	8	3	ε
⋮	⋮	⋮	⋮
hydronium	0	0	H_3O^+
hydronium	1	1	$_3O^+$
hydronium	2	1	O^+
hydronium	3	1	$^+$
hydronium	4	3	

empty string

final state

❷ Focus on parallel progress

step	compound	state	input
0	citrate	0	$C_6H_5O_7^{3-}$
0	hydronium	0	H_3O^+
1	citrate	1	$_6H_5O_7^{3-}$
1	hydronium	1	$_3O^+$
2	citrate	1	$H_5O_7^{3-}$
2	hydronium	1	O^+
3	citrate	1	$_5O_7^{3-}$
3	hydronium	1	$^+$
4	citrate	1	O_7^{3-}
4	hydronium	3	ε
5	citrate	1	$_7^{3-}$
6	citrate	1	$^{3-}$
7	citrate	2	$^{-}$
8	citrate	3	ε
⋮	⋮	⋮	⋮

Termination and Bag Semantics (UNION ALL)

The recursive CTE in regular expression matching uses **bag semantics** (UNION ALL). Will matching always **terminate**?

- Column step is increased in each iteration, thus...
  1. q^∂ **will never produce duplicate rows** and
  2. there is no point in computing the difference $q^\partial(t) \setminus r$ in $\mathrm{iterate}(q^\partial, q_0)$: $q^\partial(t) \cap r = \emptyset$.

- q^∂ **is guaranteed to evaluate to $\emptyset$ at one point**, since...
  1. one character is chopped off in each iteration and length(m.input) > 0 will yield false eventually, or
  2. the FSM gets stuck due to an invalid input character (contains(f.labels, left(m.input, 1)) yields false).

4 Recursive Array Processing: Solving Sudoku[3] Puzzles

			6				7	5
4				5		8		1
	3			7			2	
		6			1			
			7			5	8	
	9			3				6
	4				9			
		1	8			2		
							3	

- Fill in the blanks with digits $\in \{1,\ldots,9\}$ such that

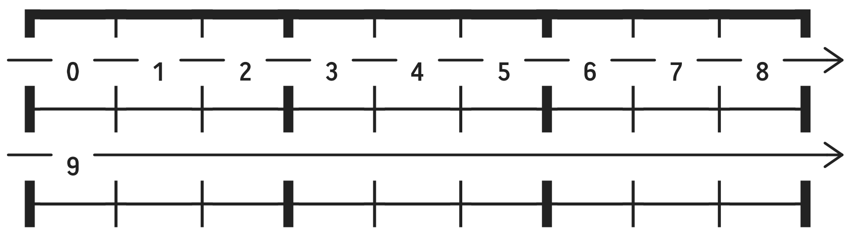
  1. no 3×3 box and
  2. no row or column

  carries the same digit twice.

- Here: encode board as digit array.

[3] Japanese: *sū(ji)+doku(shin)*, “number with single status.” (Yes, this board has a unique solution.)

Row-Major Array-Encoding of a 2D Grid



- Build row-wise `int[]` array of 81 cells ∈ {0,…,9}, with 0 ≡ blank.

- Derive **row/column/box index** from cell *c* ∈ {0,…,80}:
  - Row of *c*: `(c // 9) * 9` ∈ {0,9,18,27,36,45,54,63,72}
  - Column of *c*: `c % 9` ∈ {0,1,2,3,4,5,6,7,8}
  - Box of *c*: `((c // 3) % 3) * 3 + (c // 27) * 27` ∈ {0,3,6,27,30,33,54,57,60}

- (Clunky—But: relational encodings of grids upcoming.)

Finding All Puzzle Solutions (Query Plan)

board	blank
[5,3,0,0,7,…] ↑	$b \in \{0,\ldots,80\} \cup \{-1\}$

Table sudoku

1. **Invariant:**

   - Column board encodes a valid (but partial) Sudoku board in which the first blank (≡ 0) occurs at index b. If the board is complete, $b = -1$.

2. In each iteration, **fill in all digits** $\in \{1,\ldots,9\}$ at b and **keep all boards that turn out valid.**

Finding All Puzzle Solutions (SQL Code)

```
WITH RECURSIVE
sudoku(board, blank) AS (
 SELECT i.board, list_position(i.board, 0)-1 AS blank
 FROM   input AS i                --       ↑
                                  -- encodes blank
   UNION ALL

 SELECT              s.bd[1:s.b] || [fill] || s.bd[s.b+2:81]       AS board,
       list_position(s.bd[1:s.b] || [fill] || s.bd[s.b+2:81], 0)-1 AS blank
 FROM  sudoku AS s(bd, b), generate_series(1,9) AS _(fill)
                        --
                        --   try to fill in all 9 digits
 WHERE s.b >= 0 AND NOT EXISTS (
   SELECT NULL
   FROM   generate_series(1,9) AS __(o)
   --
   --      9 cells in row/column/box
   WHERE  fill IN (‹digits in row/column/box of s.b at offset o›))
)
```

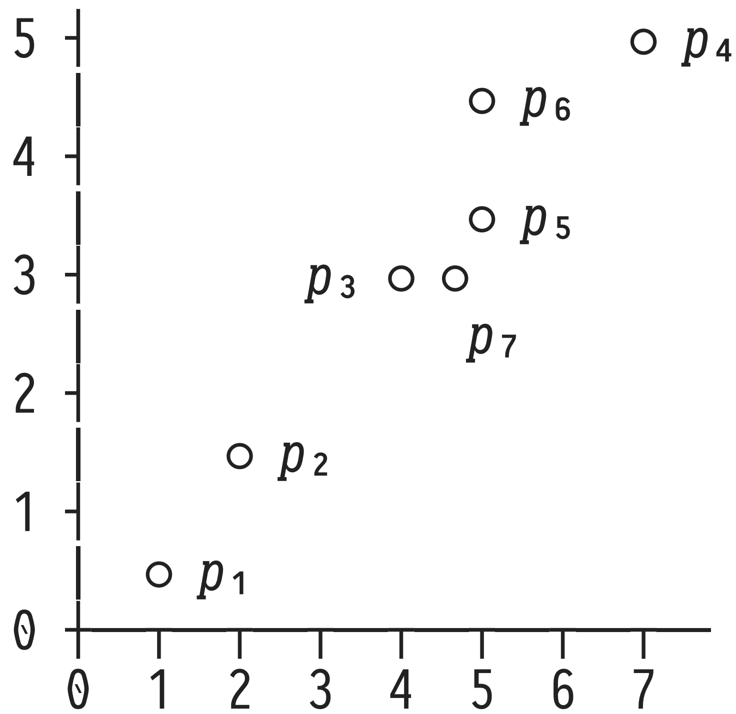
5 ¦ How SQL Can Tackle Problems in Machine Learning[4]

Most sizable *source data* for Machine Learning (ML) problems reside **inside** database systems. Actual *ML algorithms* are predominantly implemented **outside** the DBMS—Python, R, MatLab—however:

- Involves data serialization, transfer, and parsing. 👎
- The main-memory based ML libraries and programming frameworks are challenged by the data volume. 👎

Demonstrate how ML algorithms (here: **K-Means** clustering) may be expressed in SQL and thus executed close to the data.

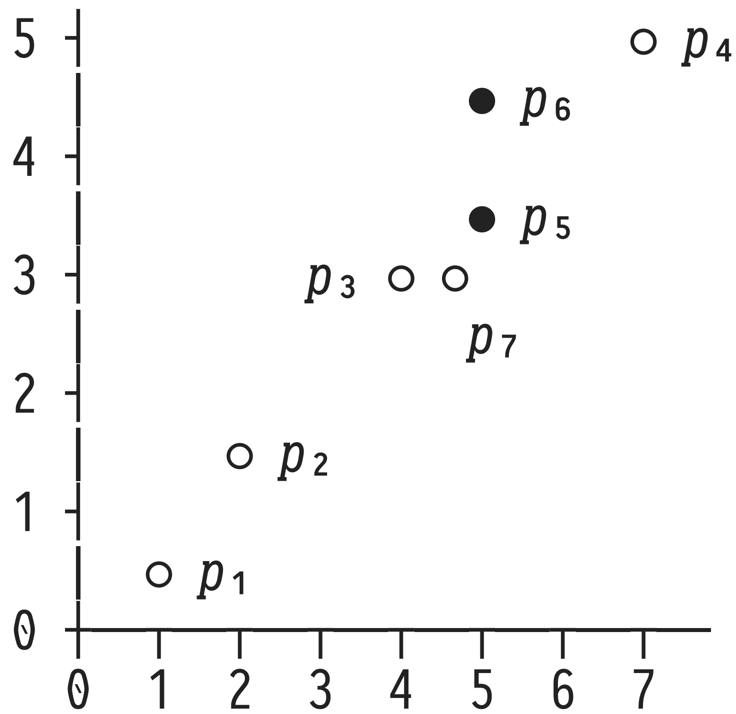
[4] I apologize for the hype vocabulary.



- **Goal:** Assign each n-dimensional point p_i to one of ***k* clusters** ($k \geqslant 2$ given).
- Once done, each p_i shall belong to the cluster with the nearest **mean** (a point that serves as "the prototype of the cluster").

K-Means is computationally difficult (NP-hard) but good approximations/heuristics exist.

K-Means: Lloyd's Algorithm with Forgy Initialization



- Pick k random points (here: p_5, p_6 for k = 2) as initial means.

1. **Update:**
   Determine k new means to be the **centroids** of the points assigned to each cluster.

2. **Assignment:**
   Assign points p_i to the cluster with the nearest mean.

Iterate 1. + 2. until assignments **no longer change.**

K-Means: Forgy Initialization (Query Plan)

<u>point</u>	loc
1	point(1.0, 1.0)
2	point(2.0, 1.5)
⋮	⋮

Table points

- Picking random rows from table *T*:

```
TABLE T
ORDER BY random()
LIMIT k                          -- pick (at most) k rows
```

```
SELECT t.*
FROM T AS t
USING SAMPLE [k ROWS | n%]       -- pick k rows | n% of all rows
```

K-Means: Lloyd's Algorithm (Query Plan)

Invariant:

iter	point	loc	cluster
i	p	l	c

Table k_means

- In iteration i, point p (at location l) has been assigned to cluster c.
    - Iteration 0 will use a sample table of k random points as cluster centroids. Iteration $i > 0$ will determine the centroids based on the point-to-cluster assignment found in iteration i-1.

K-Means: Core of the SQL Code

```
WITH RECURSIVE
⋮
k_means(iter,point,loc,cluster) AS (
  ⋮ -- ‹iteration 0 (initialization)›
    UNION ALL
  (WITH clusters(cluster,centroid) AS (
    -- 1. Update: find new cluster centers
    SELECT k.cluster, (AVG(k.loc.x), AVG(k.loc.y)) AS centroid
    FROM   k_means AS k
    GROUP BY k.cluster
   )
   -- 2. Assignment: (re-)assign points to clusters
   SELECT k.iter + 1 AS iter, k.point, k.loc,
          (SELECT ARG_MIN(c.cluster, dist(k.loc, c.centroid))
           FROM   clusters AS c) AS cluster
   FROM   k_means AS k
   WHERE  k.iter < ‹iterations›
  )
)
```

SQL Notes and Grievance (1)

- We first deconstruct and later reconstruct the 2D point locations `k.loc :: point` for centroid computation:

```
… (AVG(k.loc.x), AVG(k.loc.y)) :: point …
```

- Wanted: aggregate `AVG() :: bag(point) → point`.

  💡 In some RDBMSs, we can build **user-defined aggregates.**[5]

[5] For PostgreSQL, see `CREATE AGGREGATE` at https://www.postgresql.org/docs/current/xaggr.html.

SQL Notes and Grievance (2)

- K-Means is the prototype of an algorithm that searches for a **fixpoint**. Still, we were using UNION ALL semantics and manually maintain column iter 😳. Why?
  - To find the point-to-cluster assignment in iteration *i*, need information about *all* points in *all* clusters found in iteration *i*-1 (to determine the clusters' centroid). UNION semantics only provides the most recently changed assignments in table k_means.
  - Strictly increasing iter counter guarantees that all rows in k_means change in every iteration ⇒ good 👍, but endless recursion 👎.

💡 **SQL iteration constructs** that provide access to all rows of the previous iteration, changed or not. (Research ⚗)

7 ¦ Table-Driven Query Logic (Control Flow → Data Flow)

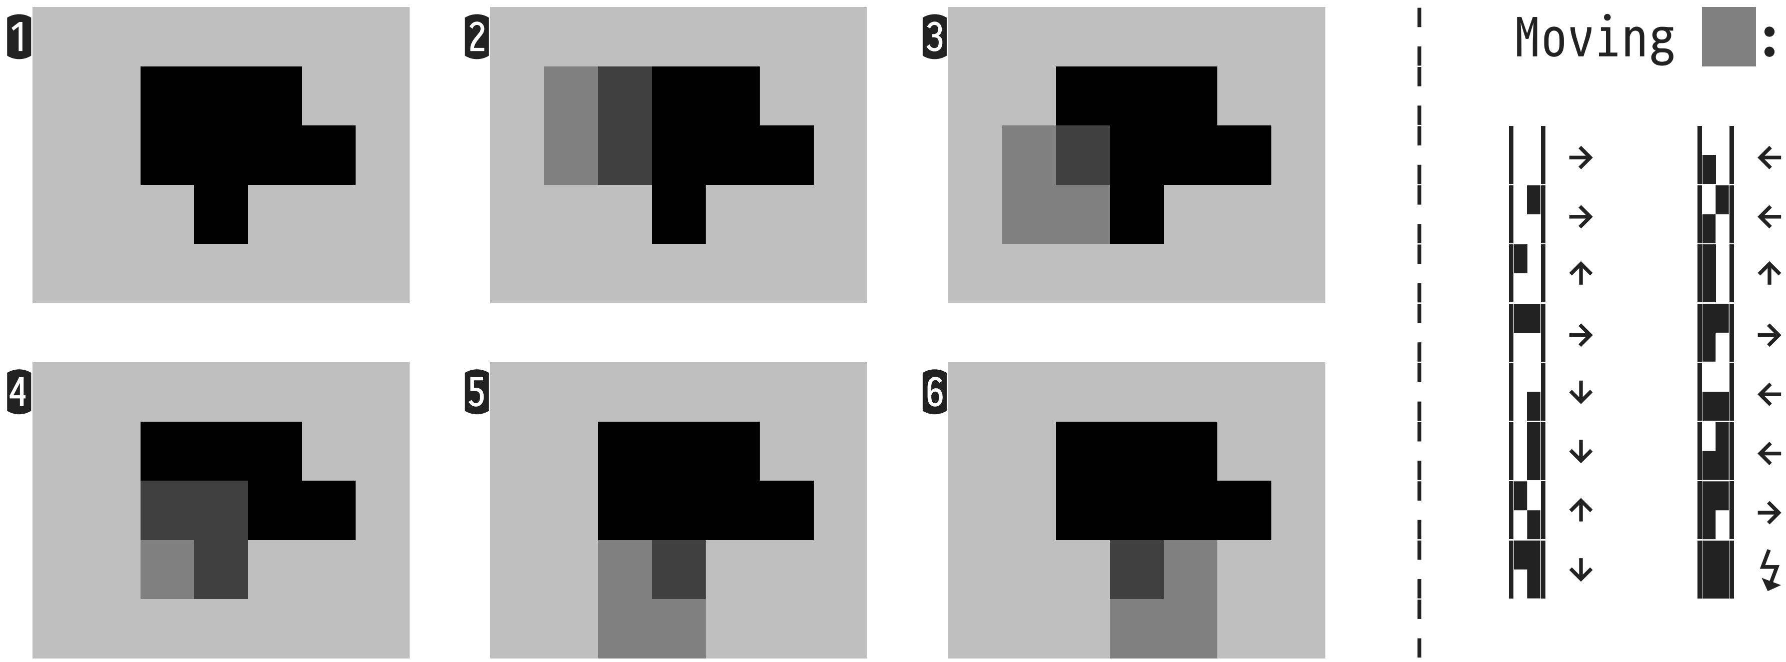
SQL provides a family of constructs to encode the **logic** (in the sense of **control flow**) of algorithms:

1. Obviously: WHERE *p*, HAVING *p*,
2. q_1 UNION ALL q_2 UNION ALL … UNION ALL q_n in which the q_i contain guards (mutually exclusive predicates p_i) that control their contribution,
3. CASE *p* WHEN … THEN … ELSE … END.

SQL being a data-oriented language additionally suggests the option to **turn control flow into data flow. Encoding query logic in tables** can lead to compact and extensible query variants.

Find Isobaric or Contour Lines: Marching Squares

Goal: Trace the boundary of the object ▀█▀ in ❶:



- **15 cases** define the movement of the 2×2 pixel mask.

Marching Squares (Query Plan)

1. **Encode mask movement** in table directions that maps 2×2 pixel patterns to $(\Delta x, \Delta y) \in \{-1,0,1\} \times \{-1,0,1\}$.
   Examples: ▛ maps to (1,0) →, ▘ maps to (0,-1) ↑.

2. For each 2D-pixel p_0, read pixels at p_0+(1,0), p_0+(0,1), p_0+(1,1), to form a 2×2 squares map [table squares].

3. Iteratively fill table march(x,y):
   - [q_0]: Start with (1,1) ∈ march.
   - [$q_{\circlearrowleft}$]: Find 2×2 pixel pattern at (x,y) in squares, lookup pattern in directions to move mask to (x,y) + $(\Delta x,\Delta y)$.

Marching Squares (SQL Code)

```
WITH RECURSIVE
⋮
march(x,y) AS (
 SELECT 1 AS x, 1 AS y
    UNION
 SELECT new.x AS x, new.y AS y
 FROM   march AS m, squares AS s,
        directions AS d,                                           ⎫
        LATERAL (VALUES (m.x + (d.dir).Δx,                         ⎬ ⁑
                         m.y + (d.dir).Δy)) AS new(x,y)            ⎪
 WHERE  (s.ll,s.lr,s.ul,s.ur) = (d.ll,d.lr,d.ul,d.ur)              ⎭
 AND    (m.x,m.y) = (s.x,s.y)
)
```

⁑ Table lookup replaces a 15-fold case distinction. 👍

8 Encoding Cellular Automata in SQL

Cellular automata (CA)[6] are discrete state-transition systems that can model a variety of phenomena in physics, biology, chemistry, maths, or the social sciences:

- **Cells** populate a regular *n*-dimensional **grid**, each cell being in one of a finite number of **states**.
- A cell can interact with the cells of its **neighborhood**.
- State of cell *c* changes from **generation to generation** by a fixed set of **rules**, dependent on *c*'s state and those of its neighbors.

[6] Discovered by Stanislaw Ulam and John von Neumann in the 1940s at Los Alamos National Laboratory.

Cell State Change in Cellular Automata

Here, we will distinguish *two flavors* of CA:

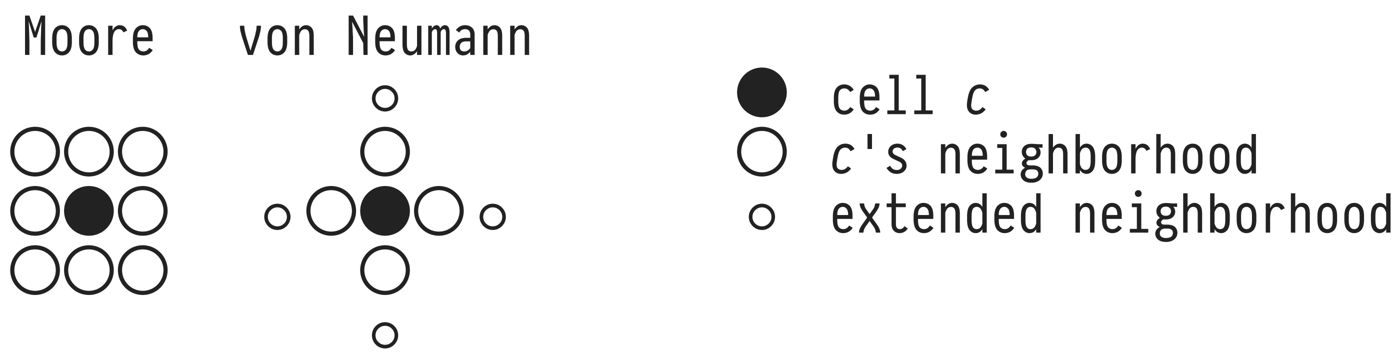
❶ Cell *c* is **influenced by** its neighborhood (*c*'s next state is a function of the cell states in the neighborhood) [Conway's *Game of Life*]	❷ Cell *c* **influences** cells in its neighborhood (*c* contributes to state changes to be made in the neighborhood) [Fluid simulation]

Both flavors lead to quite different SQL implementations. ❶ is (almost) straightforward, ❷ is more involved. Let us discuss both.

Cell Neighborhood

Cell **neighborhood** is flexibly defined, typically referring to (a subset of) a cell's *adjacent* cells:

- Types of neighborhoods, for *n* = 2 (2D grid):



x	**y**	**cell**
x	*y*	*cell state*

Table grid

Accessing the Cell Neighborhood — Variant 1

- Excerpt of code in *q*① (computes next generation of grid), access the neighbors *n* of cell *c*:

```
WITH RECURSIVE
ca(x,y,cell) AS (
  ⋮
  SELECT c.x, c.y, f(c.cell, agg(n.cell)) AS cell
  FROM   ca AS c, ca AS n -- ← ⚠ two references to ca
  WHERE  neighbors(c,n)   -- ← e.g. Moore neighborhood
  GROUP BY c.x, c.y, c.cell
  ⋮
)
```

- This a suitable CA core (*f*, *agg* encode CA rules).
- **NB.** *q*① refers to recursive table ca *more than once*.

🔧 Life — SQL Encoding of Rules (Variant 1)

- *q*⭯ uses non-linear recursion over table life:

```
WITH RECURSIVE
life(gen,x,y,cell) AS (
 ⋮
 SELECT l.gen + 1 AS gen, l.x, l.y,
        CASE (l.cell, SUM(n.cell))
            --   (c, p): c ≡ state of cell, p ≡ # of live neighbors
            WHEN (1, 2) THEN 1 -- c lives on
            WHEN (1, 3) THEN 1 -- c lives on
            WHEN (0, 3) THEN 1 -- reproduction
            ELSE             0 -- under/overpopulation
        END AS cell
 FROM   life AS l, life AS n
 WHERE  abs(l.x - n.x) <= 1         --  ⎫  neighbors(l,n)
 AND    abs(l.y - n.y) <= 1         --  ⎬  (Moore neighborhood)
 AND    (l.x, l.y) <> (n.x, n.y)    --  ⎭
 GROUP BY l.gen, l.x, l.y, l.cell
)
```

Interlude: WITH RECURSIVE — Syntactic Restrictions

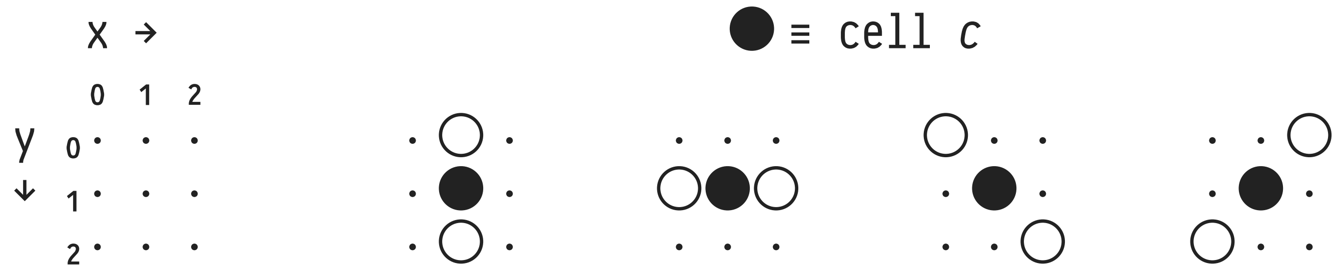
Some RDBMSs **syntactically restrict** WITH RECURSIVE queries, in particular the **references to the recursive table** T:

1. No references to T in q_0.
2. A single reference to T in q_∂ only (**linear recursion**).
3. No reference to T in subqueries outside the FROM clause.
4. No reference to T in INTERSECT or EXCEPT.
5. No reference to T in the null-able side of an outer join.
6. No aggregate functions in q_∂ (window functions *do* work).
7. No ORDER BY, OFFSET, or LIMIT in q_∂.

Enforces **distributivity:** $q_\partial(T \cup \{t\}) = q_\partial(T) \cup q_\partial(\{t\})$, allowing for incremental evaluation of WITH RECURSIVE.

Accessing the Cell Neighborhood — Variant 2

💡 **Window functions** admit access to rows in **cell vicinity:**



frame ≡

PARTITION BY	*c*.x	*c*.y	*c*.x−*c*.y	*c*.x+*c*.y
ORDER BY	*c*.y	*c*.x	*c*.x+*c*.y	*c*.x−*c*.y

ROWS BETWEEN 1 PRECEDING AND 1 FOLLOWING
EXCLUDE CURRENT ROW -- ← omit center *c*

```
SELECT … f(c.cell, agg(c.cell) OVER ( frame )) …
FROM   ca AS c(x,y,cell)
```

Conway's Game of Life

Life[7] simulates the evolution of cells c (state: either *alive* or *dead*) based on the population count $0 \leqslant p \leqslant 8$ of c's Moore neighborhood:

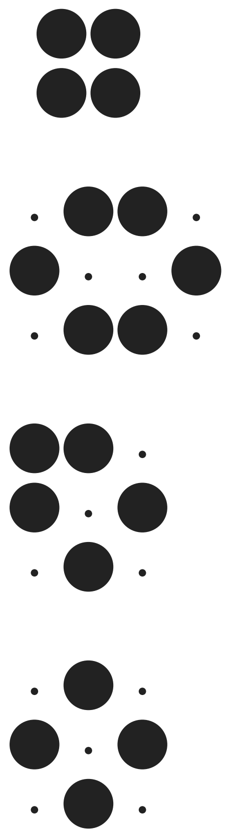
1. If c is alive and $p < 2$, c dies (underpopulation).
2. If c is alive and $2 \leqslant p \leqslant 3$, c lives on.
3. If c is alive and $3 < p$, c dies (overpopulation).
4. If c is dead and $p = 3$, c comes alive (reproduction).

Note: The next state of c is a function of the neighborhood states. c does *not* alter cell states in its neighborhood.

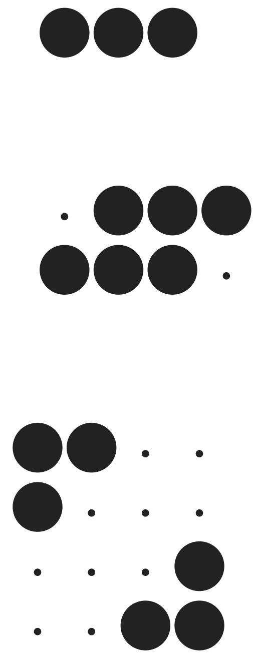
[7] John H. Conway († April 2020), column *Mathematical Games* in *Scientific American* (October 1970).

Life — A Few Notable Cell Patterns

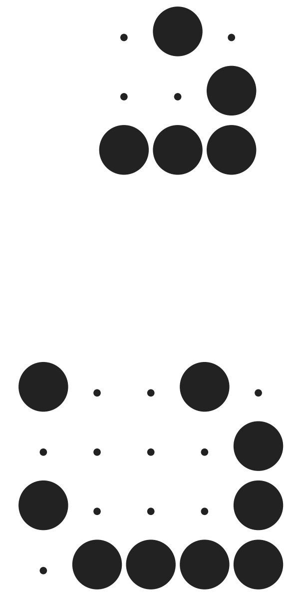
Still



Oscillators
(period: 2)



Spaceships

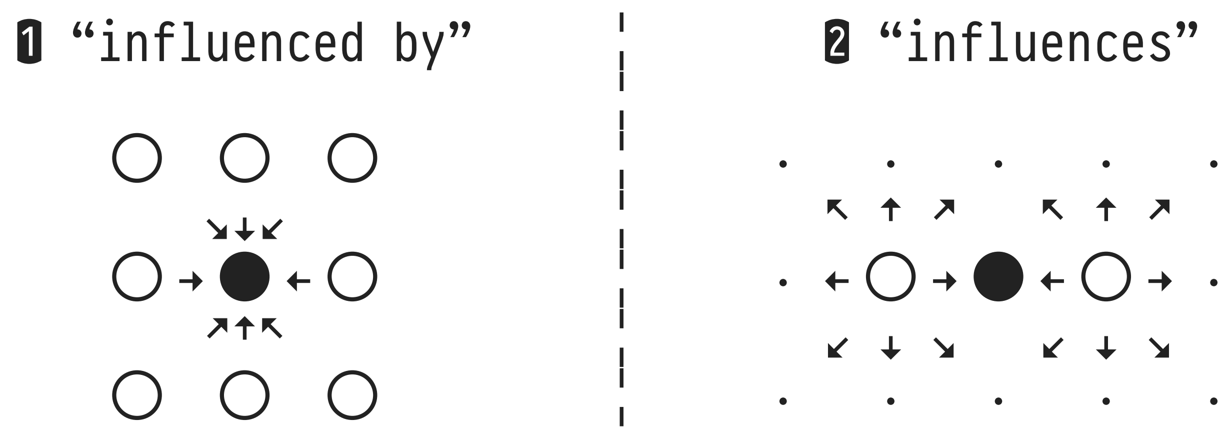


Life — SQL Encoding of Rules (Variant 2)

- *q*⟲ uses window functions to explore vicinity of *c*:

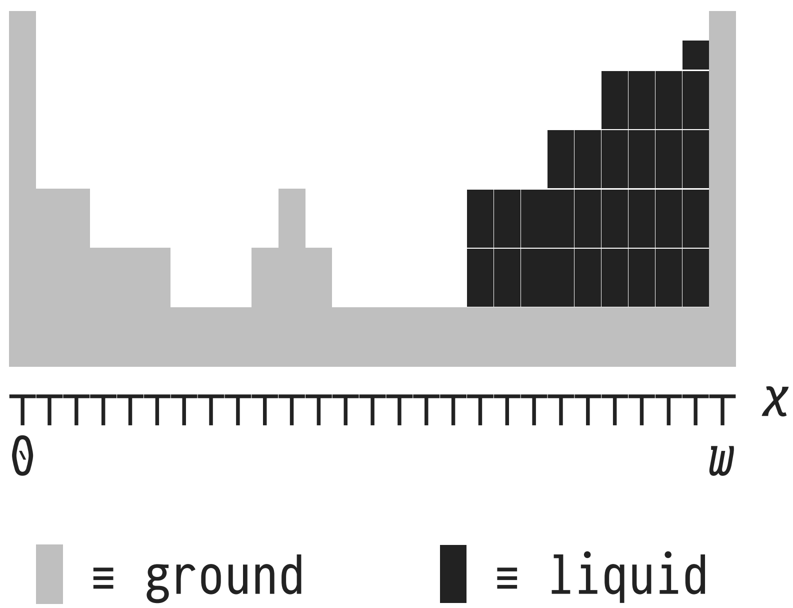
```
WITH RECURSIVE
life(gen,x,y,cell) AS (
 ⋮
 SELECT l.gen + 1 AS gen, l.x, l.y,
        CASE (l.cell, (  SUM(l.cell) OVER <horizontal ⋯>
                       + SUM(l.cell) OVER <vertical ⋮>
                       + SUM(l.cell) OVER <diagonal ⋱>
                       + SUM(l.cell) OVER <diagonal ⋰>
                      )
             )
          --   (c, p): c ≡ state of cell, p ≡ # of live neighbors
          WHEN (1, 2) THEN 1 -- ⎫
          WHEN (1, 3) THEN 1 -- ⎬ alive
          WHEN (0, 3) THEN 1 -- ⎭
          ELSE             0 -- dead
        END AS cell
 FROM life AS l
 ⋮
)
```

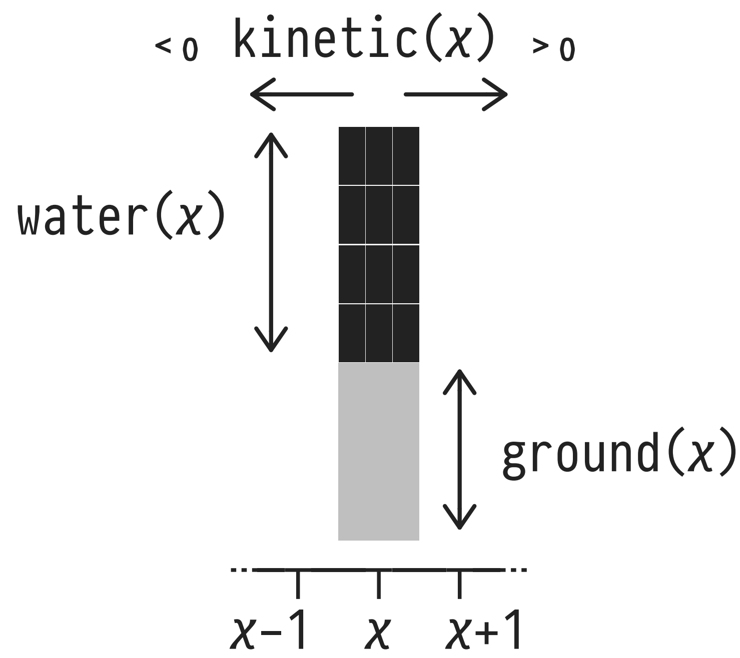
If cells assume an **active role** in influencing the next generation, this suggests a different SQL implementation.



- In type ❷, cells ○ actively influence their neighbors. Affected cells ● need to **accumulate** these individual influences (up to 8 in this grid—only two shown here).

Simulate the Flow of Liquid (in a 1D Landscape)





Goal: Model two forms of energy in this system:

- **potential energy** at x (**pot**(x) ≡ ground(x) + water(x))
- left/right **kinetic energy** at x (**kinetic**(x))

Liquid Flow: Cellular Automaton[8]

```
Δwater ← (0,0,…,0)  -- changes to water and energy levels at x
Δkin   ← (0,0,…,0)  --   in next generation
for x in 1…w-1:
│ -- liquid flow to the left?
│ if pot(x)-kin(x) > pot(x-1)+kin(x-1):           -- force ← > force →
│ │ flow ← ¼ × min(water(x), pot(x)-kin(x)-(pot(x-1)+kin(x-1)))
│ │ Δwater(x-1) ← Δwater(x-1)+flow                -- ⎫ aggregate the
│ │ Δwater(x)   ← Δwater(x)  -flow                -- ⎬ influences on
│ └ Δkin(x-1)   ← Δkin(x-1) - ½×kin(x-1) - flow   -- ⎭ cells @ x / x-1
│ -- liquid flow to the right?
│ if pot(x)+kin(x) > pot(x+1)-kin(x+1):           -- force → > force ←
│ ⋮  -- "mirror" the above code
└
water ← water + Δwater        -- ⎫ apply the aggregated influences
kin   ← kin   + Δkin          -- ⎭ to all cells (ground is constant)
```

[8] CA rules adapted from those posted by user *YankeeMinstrel* on the *Cellular Automata* 👽. $\frac{1}{4}$, $\frac{1}{2}$ are (arbitrary) dampening/friction factors. See https://www.reddit.com/r/cellular_automata/.

CA with Neighborhood Influencing Rules: SQL Template

```
WITH RECURSIVE
cells(iter,x,y,state) AS (
 ⋮
 SELECT  c0.iter + 1 AS iter, c0.x, c0.y,
         c0.state ⊕ COALESCE(agg.Δstate, z) AS state
 FROM    cells AS c0 LEFT OUTER JOIN
         -- find and aggregate influences on all cells @ x,y
 LATERAL (                                 -- ⎫     encodes rules
          ) AS agg(x,y,Δstate)             -- ⎭     of the CA
         -- extract all influences on cell c0 (□ if none)
         ON (c0.x, c0.y) = (agg.x, agg.y)
 WHERE   c0.iter < ‹iterations›
)
```

- Design: no agg(x,y,_) if cell @ x,y doesn't change state.
- Assume that z is neutral element for ⊕: $s \oplus z = s$.

CA: From Individual to Aggregated Influences (SQL Template)

```
⋮
SELECT c0.iter + 1 AS iter, c0.x, c0.y,
       c0.state ⊕ COALESCE(agg.Δstate, z) AS state
FROM   cells AS c0 LEFT OUTER JOIN
       -- find and aggregate influences on all cells @ x,y
       (SELECT infs.x, infs.y, agg(infs.Δstate) AS Δstate
        FROM   (
                        ) AS infs(x,y,Δstate)
        GROUP BY infs.x, infs.y
       ) AS agg(x,y,Δstate)
       -- extract all influences on cell c0 (□ if none)
       ON (c0.x, c0.y) = (agg.x, agg.y)
⋮
```

- $(x,y,\Delta state) \in$ infs: individual influence on cell @ x,y.
- Typically, we will have $agg = (\phi,\ z,\ \oplus)$.

CA: Individual Neighborhood Influences (SQL Template)

```
⋮
-- find and aggregate influences on all cells @ x,y
(SELECT infs.x, infs.y, agg(infs.Δstate) AS Δstate
 FROM   (SELECT          -- ⎱ all influences that c1 has on
                         -- ⎰ its neighborhood (≡ CA rules)
         FROM   cells AS c1) AS inf(influence),
         LATERAL unnest(inf.influence) AS infs(x,y,Δstate)
 GROUP BY infs.x, infs.y
) AS agg(x,y,Δstate)
⋮
```

- For each cell c1, computes a **list of influence** influence with elements (x,y,Δstate): c1 changes the state of cell @ x,y by Δstate.
- For each c1, influence may have 0, 1, or more elements.

CA: Encoding Neighborhood Influencing Rules (SQL Template)

```
⋮
(SELECT (CASE WHEN p1 THEN                    -- if p1 holds, then c1 has…
                   [(c1.x-1, c1.y, ),        -- influence on ← cell
                     (c1.x, c1.y+1, )]       -- influence on ↓ cell
          END
      || CASE WHEN p2 THEN
                   [(c1.x, c1.y, )]           -- influence on c1 itself
          END --    ↑     ↑     ↑
           ⋮  --    x     y  Δstate
        ) AS influence
 FROM   cells AS c1
 WINDOW horizontal AS …  -- } provide frames to access neighbors
 WINDOW vertical   AS …  -- } of c1 in pi, , , and
) AS inf(influence)
⋮
```

- Admits straightforward transcription of rules into SQL.

CA: Summary of Influence Data Flow (Example)

- Assume Δstate :: int, *agg* ≡ SUM (*i.e.*, *z* ≡ 0, ⊕ ≡ +):

❶ Table **inf**

influence
[(1,3,+4),(1,4,-2)]
[(1,3,-3),(1,3,+1)]
[(2,2,-5)]
[(1,4,+2)]

neighborhood influence, computed based on current cell generation

❷ Table **infs**

x	y	Δstate
1	3	+4
1	3	-3
1	3	+1
1	4	-2
1	4	+2
2	2	-5

❸ Table **agg**

x	y	Δstate
1	3	+2
1	4	0
2	2	-5

apply to current cell states using ⊕ to find next generation

Liquid Flow (SQL Code)

```
WITH RECURSIVE
sim(iter,x,ground,water,kinetic) AS (
  SELECT 0 AS iter, f.x, f.ground, f.water, 0.0 AS kinetic
  FROM   fluid AS f

    UNION ALL

  SELECT s0.iter + 1 AS iter, s0.x, s0.ground,
         s0.water   + COALESCE(agg.Δwater  , 0) AS water,
         s0.kinetic + COALESCE(agg.Δkinetic, 0) AS kinetic
  FROM   sim AS s0
          LEFT OUTER JOIN
        LATERAL (SELECT infs.xwk.x, SUM(infs.xwk.Δwater) AS Δwater, SUM(infs.xwk.Δkinetic) AS Δkinetic
                 FROM   (SELECT (-- flow to the left                            --
                                 CASE WHEN ‹p₁›                                 --
                                 THEN [{x:s1.x-1, Δwater:…, Δkinetic:…},        --
                                       {x:s1.x  , Δwater:…, Δkinetic:…},        --
                                       {x:s1.x-1, Δwater:…, Δkinetic:…}         --
                                       ]                                        --
                                 END                                            --
                                 ||                                             --
                                 -- flow to the right                           --
                                 CASE WHEN ‹p₂›                                 --
                                 THEN [{x:s1.x+1, Δwater:…, Δkinetic:…},        --
                                       {x:s1.x  , Δwater:…, Δkinetic:…},        --
                                       {x:s1.x+1, Δwater:…, Δkinetic:…}         --
                                      ]                                         --
                                 END                                            --
                               ) AS influence
                         FROM   sim AS s1
                         WINDOW horizontal AS (ORDER BY s1.x)
                        ) AS inf(influence),
                        LATERAL unnest(inf.influence) AS infs(xwk)
                 GROUP BY infs.xwk.x
                 ) AS agg(x, Δwater, Δkinetic)
                 ON (s0.x = agg.x)
  WHERE  s0.iter < ‹iterations›
)
SELECT s.iter, s.x, s.ground, s.water
FROM   sim AS s
ORDER BY s.iter, s.x;
```

Specific rules for the Liquid Flow CA, the enclosing SQL code is generic.

- Use **CASE** ⋯ **WHEN** ⋯ **THEN** ⋯ **END** to implement conditional rules.
- Use windows to access cell neighborhood.
- Use list concatenation (||) to implement sequences of rules.

One of *the* classic problems in Computer Science: **parsing.**

- Given the productions of a **context-free grammar**, can the input string be parsed (≡ generated) by the grammar?

```
start symbol  production rule (lhs→rhs)
         ↓    ↓
      Expr → Expr Plus Term | Term
      Term → Term Mult Fact | Fact
      Fact → [0-9]+             ↑
      Plus → [+]             choice
      Mult → [×]
         ↑      ↑
non-terminal    terminal (reg.exp.)
```

Grammar for simple arithmetic expressions:

- operators +/×, literals,
- +/× left-associative,
- op precedence: × > +.

Chomsky Normal Form and Parse Trees

We consider grammars in **Chomsky Normal Form** only: rules read *lhs → terminal* or *lhs → non-terminal non-terminal*.

```
Expr → Expr Sum
Expr → Term Prod
Expr → [0-9]+
Term → Term Prod
Term → [0-9]+
Sum  → Plus Term
Prod → Mult Fact
Fact → [0-9]+
Plus → [+]
Mult → [×]
```

Parse tree for input 2+5×8:

```
              Expr
             /    \
            /      Sum
           /      /   \
          /      /     Term
         |      /     /    \
         |     |     /      Prod
         |     |    |      /    \
       Expr  Plus  Term  Mult  Fact
         |     |    |     |     |
         2     +    5     ×     8
```

A Tabular Encoding of Chomsky Grammars

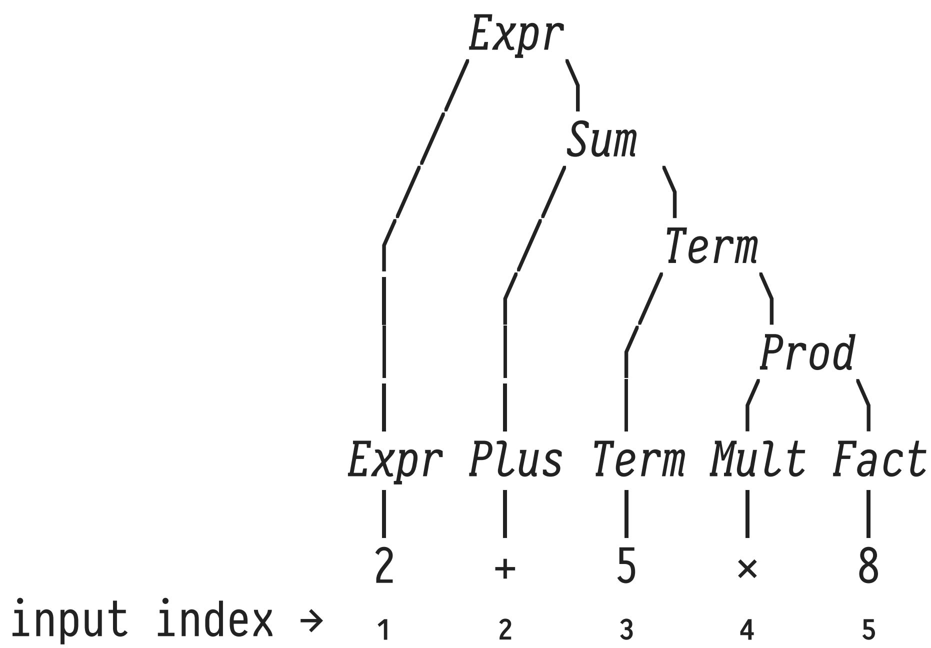
Simple encoding of the sample arithmetic expression grammar:

lhs	sym	rhs_1	rhs_2	start?
Expr	□	*Expr*	*Sum*	true
Expr	□	*Term*	*Prod*	true
Expr	[0-9]+	□	□	true
Term	□	*Term*	*Prod*	false
Term	[0-9]+	□	□	false
Sum	□	*Plus*	*Term*	false
Prod	□	*Mult*	*Fact*	false
Fact	[0-9]+	□	□	false
Plus	[+]	□	□	false
Mult	[×]	□	□	false

- Exploits that rules can have one of two forms only.
- Embedded FD lhs → start? identifies one non-terminal as the grammar's start symbol (here: *Expr*).

Building a Parse Tree, *Bottom Up*

Invariant: Keep track of which part of the input (index *from* to *to*) can be generated by the *lhs* of a rule:



lhs	from	to
Expr	1	1
Plus	2	2
Term	3	3
Mult	4	4
Fact	5	5
Prod	4	5
Term	3	5
Sum	2	5
Expr	**1**	**5**

← indicates parse successful

start symbol

spans entire input

Building a Tree in Layers Requires Access to the Past

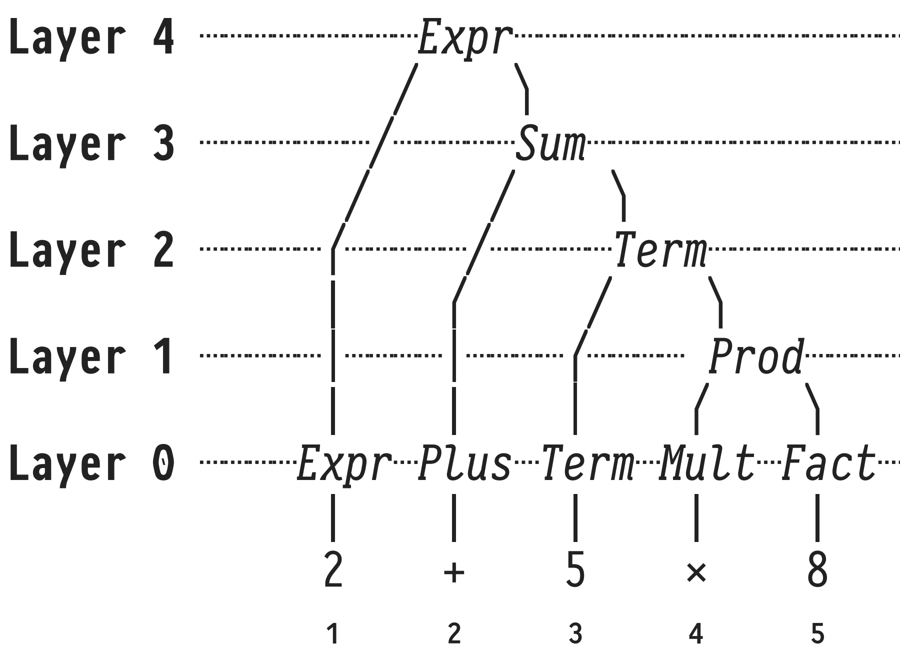


Table **parse**

lhs	from	to	
Expr	1	5	← iteration #4
Sum	2	5	← iteration #3
Term	3	5	← iteration #2
Prod	4	5	← iteration #1
Expr	1	1	
Plus	2	2	found in
Term	3	3	iteration #0
Mult	4	4	
Fact	5	5	

- To establish *Term* at **Layer 2** (iteration #2), we need *Prod* (**Layer 1**, iter #1 ✓) and *Term* (**Layer 0**, iter #0 ϟ).

▨ ≡ row added by re-injection ⁂

Parsing: Cocke-Younger-Kasami Algorithm (CYK)

The **CYK algorithm** builds parse trees bottom up, relying on formerly discovered partial parses (dynamic programming):

- Iteratively populate table `parse(lhs,from,to)`:
  - $[q_0]$: For each *lhs* → *terminal*: if *terminal* is found at index *from*…*to* in input, add (*lhs*,*from*,*to*) to `parse`.
  - $[q_{\circlearrowleft}]$: For each pair $(lhs_1, from_1, to_1)$, $(lhs_2, from_2, to_2)$ in `parse` × `parse`:[9] add $(lhs_3, from_1, to_2)$ if
    1. $to_1 + 1 = from_2$ and
    2. $lhs_3 \rightarrow lhs_1\ lhs_2$.

[9] Implies a self-join of `parse`, leading to non-linear recursion.

Parsing Using CYK (Core SQL Code)

```
WITH RECURSIVE
tokens(tok, i) AS (
  -- row (tok,i): token tok occurs at index i in input
),
parse(…, lhs, "from", "to") AS (
  SELECT …, g.lhs, t.i AS "from", t.i AS "to"
  FROM   tokens AS t, grammar AS g
  WHERE  t.tok ~ g.sym

    UNION ALL

  ⋮                                 -- ⚠ re-injection of parse omitted
  SELECT …, g.lhs, l."from", r."to"
  FROM   grammar AS g,
         parse AS l, parse AS r     -- identify two partial parses…
  WHERE  l."to" + 1 = r."from"      -- …that are adjacent in the input
  AND    (g.rhs1, g.rhs2) = (l.lhs, r.lhs)
  ⋮                                 -- ⚠ stop condition omitted
)
```
